### INTRODUCTION

This report presents the findings of a study to assess the off-site, economic benefits of conservation practices for reducing wind erosion in New Mexico. The study seeks to determine where the greatest returns from conservation programs are likely and the magnitude of anticipated returns. The study is a follow-up to an earlier study which determined the off-site costs of wind erosion in New Mexico [2].

The findings of this study include: (1) a wind erosion damage function which relates on-site erosion rates with off-site costs, (2) use of the damage function to determine the distribution of off-site costs by county, (3) projections of off-site costs over time by MLRA and county, and (4) measurements of off-site benefits of conservation practices.

A strong case exists for making off-site costs of wind erosion the principle focus of erosion control policy in New Mexico. First, the off-site costs of wind erosion dwarf the onsite costs. Annual on-site costs of wind erosion have been estimated to be \$10 million [1], while off-site costs are estimated to equal nearly \$466 million annually [2]. Second, farmers and ranchers have little incentive to control off-site costs. While they have an economic incentive to control on-site costs whenever control costs are less than the damage costs, but they have no comparable incentive to control off-site costs which they do not bear them.

Moreover, it has been argued that targeting will increase the efficiency of soil conservation programs. That is, soil conservation expenditures should be targeted to those areas having the greatest problems in order to produce the greatest net returns. In fact, a national program to target conservation efforts was initiated by U.S.D.A. in 1981 [4].

The results of this study provide information necessary for targeting soil conservation efforts to sources of off-site costs in New Mexico. It provides estimates of potential returns from targeting specific geographic areas and from using specific conservation practices.

The wind erosion damage function developed in the next section specifies the relationship between off-site costs and onsite erosion rates. This damage function provides the basis in for identifying geographic locations (i.e., counties) with the greatest off-site costs of wind erosion and for projecting off-site costs as a function of changing population and erosion rates. In particular, it provides estimates of returns from erosion rate reductions in specific geographical areas of the state. Finally, the returns from the expansion of current conservation programs are estimated for different land classifications by MLRA.

### DAMAGE FUNCTION

A wind erosion damage function relating off-site costs with on-site erosion rates was developed using a multiple regression analysis and the data base collected in the previous study of off-site costs of wind erosion in New Mexico [2]. After exhaustive testing of alternative specifications of the damage function, the following equation was found to be the best:

$$Z = e^{3.8379} X^{0.3092} Y^{0.7044}$$
 (1)

where: Z = off-site costs in millions of dollars,

X = wind erosion in tons per acre, and

Y = income in billions of dollars.

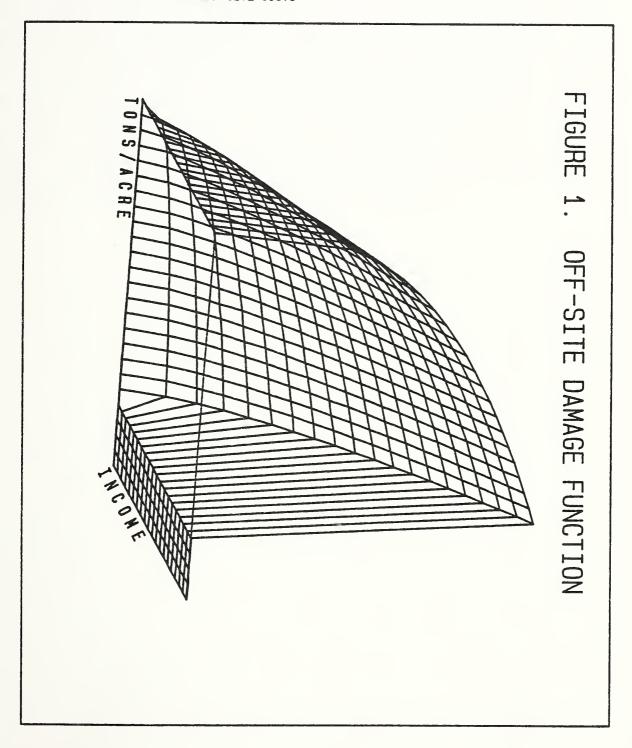

The equation explains 91 percent of the variation in off-site costs and the t-values, shown in parentheses, are significant at the 0.1 and 0.05 levels, respectively.

The income variable is a composite of the population and the per capita income of that population. That is, off-site costs of wind erosion depend upon both the number of persons impacted by blowing sand and dust and the value of the property affected per person, for which per capita income provides a proxy measure.

A three dimensional plot of Equation (1) is shown in Figure 1. Off-site costs increase at a decreasing rate with both the rate of wind erosion and income. In fact, from Equation (1) it can be seen that a 1 percent increase in the wind erosion rate will increase off-site costs by 0.3 percent and a 1 percent increase in income will increase off-site costs by 0.7 percent.

OFF-SITE COSTS

The main shortcoming of the damage function is that it treats all wind erosion and all property at risk alike. It is likely, however, that erosion nearer population centers is responsible for greater off-site costs than erosion occuring further away and that property on the periphery of cities incurs greater costs than property more protected within the city. But such distinctions require a transport model for the wind erosion and, while many models exist for localized soil movements, none has been found to predict the soil movements necessary for this study. Further research is needed to fine tune the damage function to account for such locational factors.

### DISTRIBUTION OF OFF-SITE COSTS

It is anticipated that returns from conservation programs can be maximized by targeting those areas with the greatest damages. Therefore, the damage function is used to determine the distribution of estimated off-site costs by MLRA among the counties comprising those areas.

Table 1 summarizes the input and output values of the damage function. Population and per capita income values are from the Census of Population; the average erosion rates are derived from the National Resources Inventory (NRI) computer tapes for New Mexico [3].

The estimated off-site costs by MLRA were derived in the previous study [2]. The damage function is used to predict the share of the MLRA's off-site costs to be distributed to each county within the MLRA. The distribution of off-site costs by county are summarized in Figures 2 and 3.

It can be seen from Figures 2 that over 55 percent of the off-site costs in the state are incurred in MLRA 42 and, within MLRA 42, Bernalillo County accounts for nearly 50 percent of the damages. In fact, the \$128 million of off-site damages in Bernalillo County represents nearly 28 percent of total off-site damages for the state.

Figure 2 also indicates that five counties account for over 50 percent of the state's off-site costs from wind erosion.

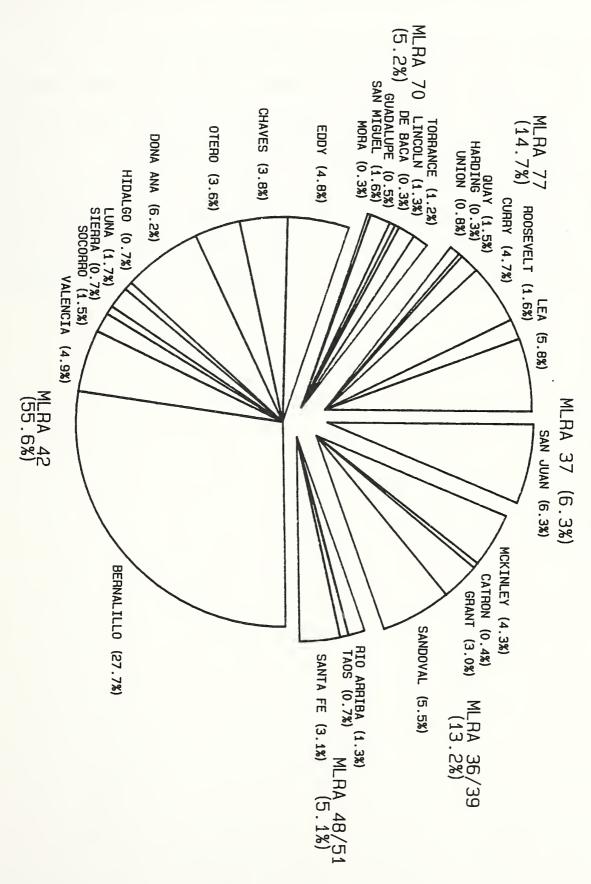

Bernalillo and Dona Ana counties in MLRA 42, San Juan County in

MLRA 37, Lea County in MLRA 77, and Sandoval County in MLRA 36/39 together account for 51.5 percent of the state's off-site wind erosion costs.

Figure 3 shows a map of the counties in New Mexico and the estimated off-site costs of wind erosion in each county. Nine counties have annual off-site costs in excess of \$20 million:

Bernalillo, Valencia, McKinley, Sandoval, San Juan, Dona Ana,

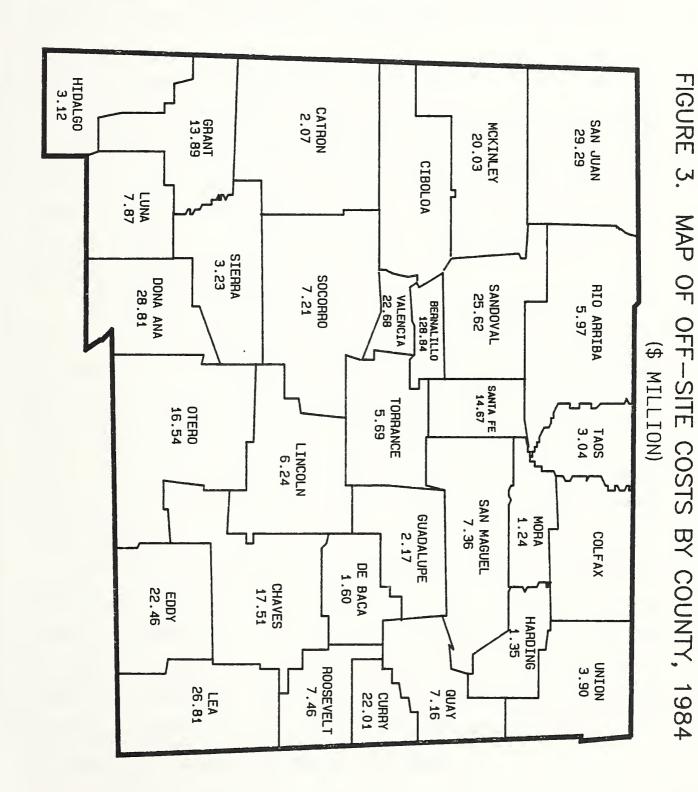

Eddy, Lea and Curry counties. At the other end of the spectrum,

twelve counties have estimated annual off-site costs of less than

\$5 million: Union, Sierra, Hidalgo, Taos, Guadalupe, Catron,

DeBaca, Harding, Mora, Colfax, Los Alamos and Ciboloa counties.

### PROJECTION OF OFF-SITE COSTS

The damage function can also be used to project off-site costs as either a function of changing population or erosion rates.

### EFFECTS OF CHANGING POPULATION

Population projections by MLRA and county are shown in Table 2. Assuming constant erosion rates and per capita incomes, these projections are used in the damage function to predict off-site costs for the period from 1984 to 2005, as shown in Table 3. Figure 4 summarizes these projections by MLRA and Figures 5 through 9 summarize them by county.

For example, the population of MLRA 42 is predicted to increase from 832,000 in 1985 to 1,129,000 in 2005, or an increase of 297,000 people (36 percent). If erosion rates and per capita incomes within MLRA remain unchanged, then this population growth will result in a growth of annual off-site costs from \$258.27 million in 1985 to \$320.16 million in 2005, or an increase of nearly \$63 million (24 percent), as shown in Table 3 and Figure 4.

Moreover, the population of Bernalillo County is expected to grow from 470,200 in 1985 to 621,200 in 2005, or by 151,000 persons (32 percent). Again assuming unchanged erosion rates and per capita incomes, this population growth can be expected to cause annual off-site costs to increase from approximately \$128.84 million in 1985 to \$156.77 in 2005, an increase of \$28 million (22 percent), as shown in Table 3 and Figure 7.

19

The data contained in Table 3 and Figures 4 through 9 clearly show that MLRA 42 has the greatest level of off-site costs from wind erosion and the greatest amount of predicted growth in these costs, and that within MLRA 42, Bernalillo County has the both the highest level and greatest predicted growth of off-site costs.

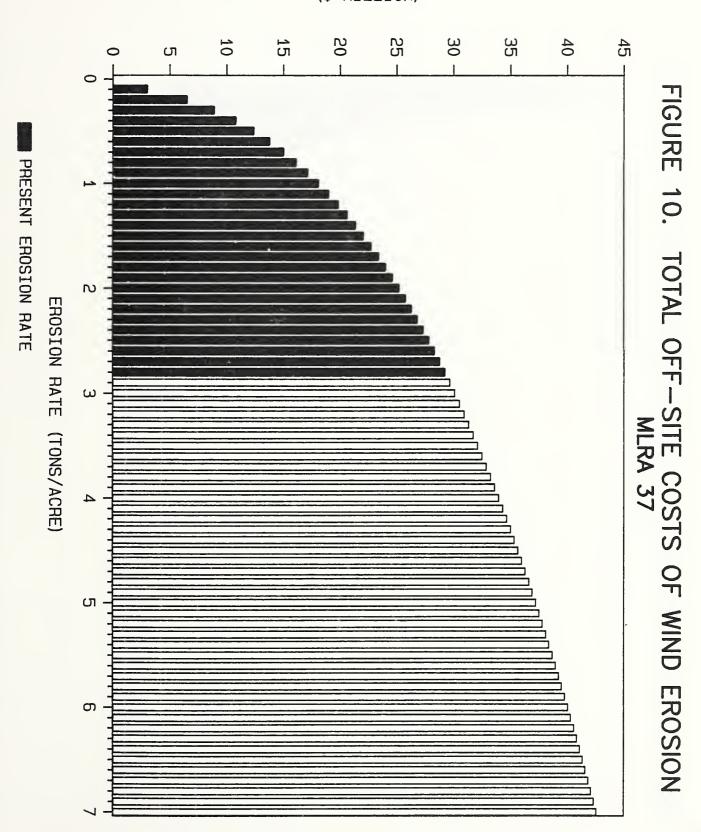

### EFFECTS OF CHANGING EROSION RATES

Alternatively, if population and per capita incomes are held constant, then the damage function can be used to predict offsite costs resulting from varying erosion rates. Figures 10, 12, 14, 16, 18 and 20 show the predicted, total, off-site costs by MLRA for different erosion rates, when the value of the property at risk is held constant. Figures 11, 13, 15, 17, 19 and 21 show the corresponding marginal, off-site costs for different erosion rates. That is, the marginal cost relations show the addition (or reduction) to total off-site costs from an addition (or reduction) to the erosion rate.

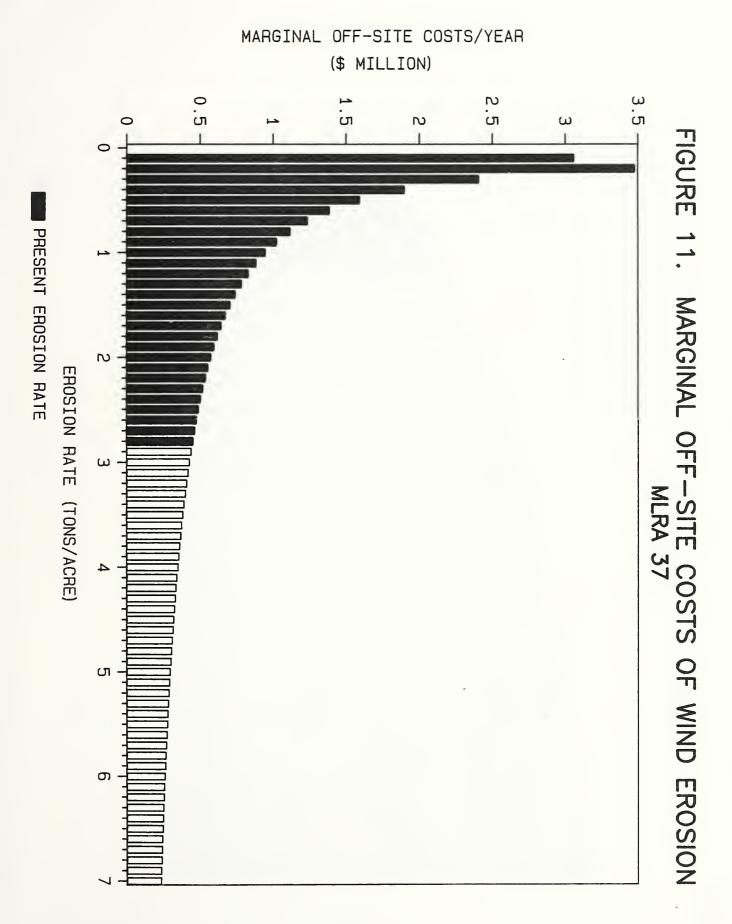

The fact that the slopes of the total off-site cost functions decline as the erosion rate increases implies that costs do not increase proportionately with erosion.

Alternatively, this implies that a reduction in wind erosion will yield a less than proportional decrease in off-site costs and that the greatest reductions in off-site costs will be associated with reductions in low rather than high erosion rates. This relationship is also shown by the marginal off-site cost functions.

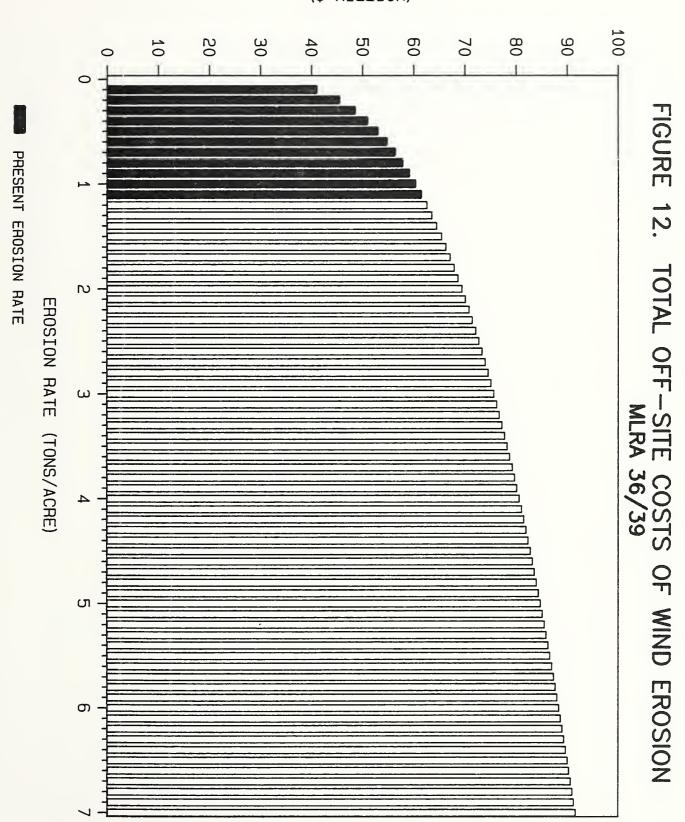

TOTAL OFF-SITE COSTS/YEAR (\$ MILLION)

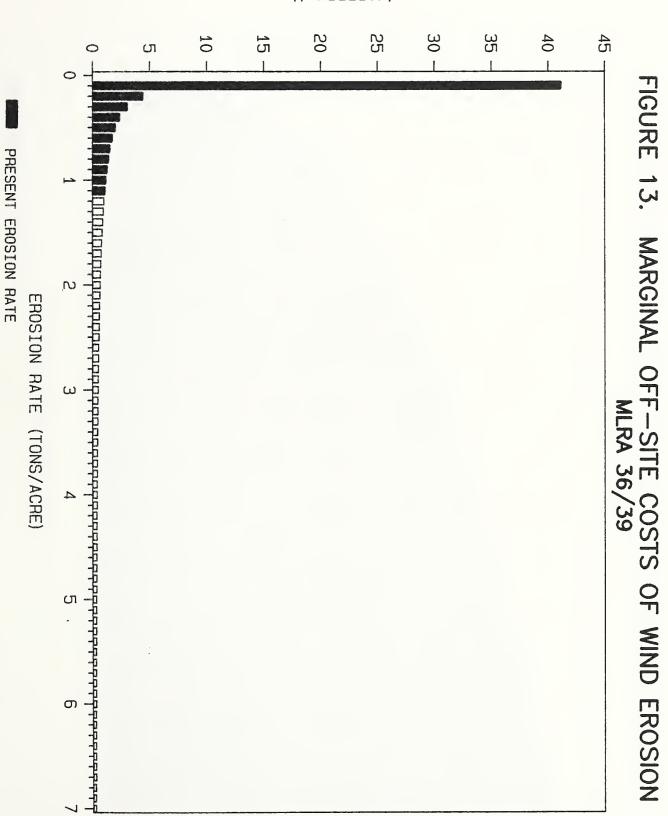

TOTAL OFF-SITE COSTS/YEAR (\$ MILLION)

TOTAL OFF-SITE COSTS/YEAR (\$ MILLION)

## MARGINAL OFF-SITE COSTS/YEAR (\$ MILLION)

For example, the total off-site cost function shown for MLRA 42 in Figure 16 indicates that reducing erosion by 2 tons/acre from the present level of 6.1 tons/acre to 4.1 tons/acre will reduce off-site costs from \$258.27 million to \$229.85 million, or \$28.42 million, but reducing erosion by 2 tons/acre from 2.1 tons/acre to 0.1 tons/acre will reduce off-site costs from \$189.22 million to \$81.39 million, or \$107.83 million.

Alternatively, the marginal off-site cost function shown for MLRA 42 in Figure 17 indicates that reducing erosion from 6.1 tons/acre to 4.1 tons/acre will reduce off-site costs by the area of the bars between these two erosion rates (i.e., \$28.42 million), but that reducing erosion from 2.1 tons/acre to 0.1 tons/acre will reduce off-site costs by the larger area of the bars between these two erosion rates (i.e., \$107.83 million).

Moreover, Figure 17 indicates the off-site benefits in MLRA 42 of each tenth of a ton/acre reduction in the erosion rate. For example, reducing the erosion rate from 0.3 to 0.2 tons/acre decreases off-site costs by the height of the bar above 0.3 tons/acre in Figure 17 or \$11.4 million. Reducing the erosion rate from 0.2 to 0.1 tons/acre reduces off-site costs by \$16.5 million and so on. The first 0.1 ton/acre of wind erosion causes \$81.4 million or nearly 32 percent of the total \$258.27 million of off-site costs in MLRA 42, while the last 0.1 ton/acre of erosion (i.e., the 6.1th ton/acre) contributes only \$1.2 million or less than 0.5 percent of the total off-site costs.

## BENEFITS OF CONSERVATION PRACTICES

A statistical analysis of the NRI data [3] provides specific information on the effectiveness of various conservation practices. By applying the observed reductions in wind erosion due to differing conservation practices to lands without those practices, decreases in erosion rates and, consequently, off-site costs can be estimated. Table 4 and Figure 22 summarize the results in terms of total expected benefits.

Rangeland is the predominate source of off-site costs from wind erosion, accounting for nearly \$402 million of the \$430 million attributable to rangeland and cropland. The principle conservation measure utilized on rangeland in New Mexico is to develop proper grazing practices. This may entail the cost of fencing or, merely, of moving salt licks on a regular basis. The expected off-site benefits from implementing proper grazing on land without these practices are shown in Table 4 and range from \$2.6 million in MLRA 48/51 to \$106 million in MLRA 42. Benefits are computed by both land capability classification and by the rate of erosion on the land (i.e., >T and >2T). These estimates do not include benefits to rangeland which is untreatable due to steep slopes or other geological or climitalogical conditions that make treatment unfeasible.

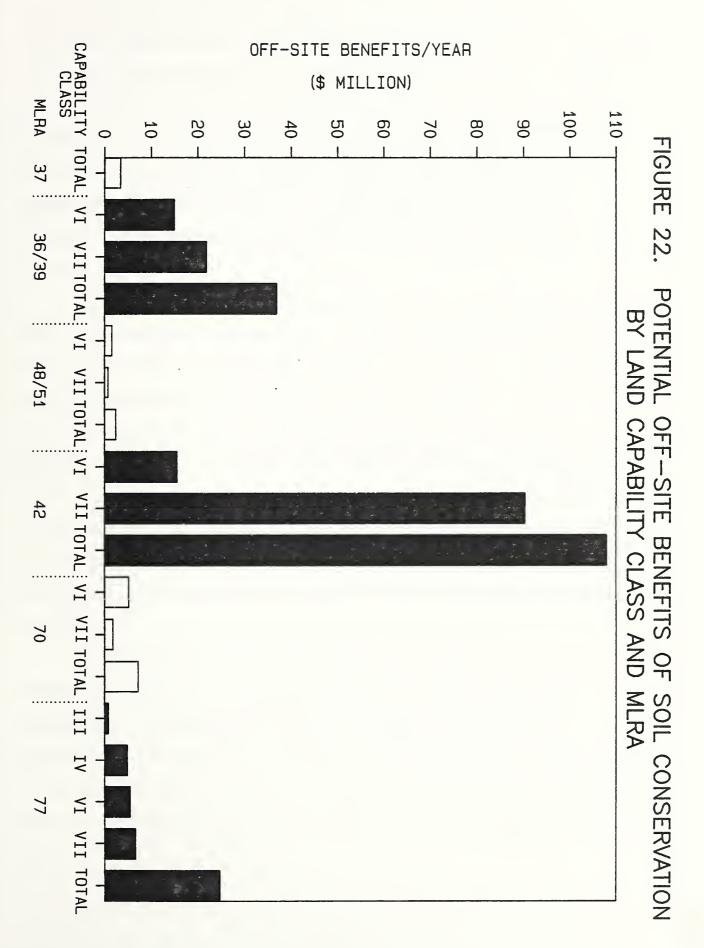

Data for assessing the effectiveness of conservation practices on cropland is insufficient for all MLRA's except 42 and 77. Approximately 95 percent of the cropland in MLRA 42 is irrigated, with the predominate conservation practice being some form of irrigation water management. These conservation

Note: 8lanks indicate that insufficient data exists for statistically significant results.

practices are primarily directed towards saving water and reducing water erosion, but some wind erosion benefits are also realized. Approximately 66 percent of the cropland in MLRA 77 is nonirrigated, with the predominate conservation practice being conservation tillage. Irrigation water management is also practiced and reduces, to some extent, wind erosion. The expected off-site benefits of reductions in wind erosion resulting from conservation practices are also summarized in Table 4.

The costs of conservation practices on such a broad scale may be impossible to determine. Proper grazing practices may cost practically nothing or as much as \$20/acre. Irrigation water management costs are also highly variable. Conservation tillage actually costs less than conventional tillage on an annual basis and the initial conversion costs may be covered in as little time as one year. Rather than estimate the costs of conservation, the approach taken here is to calculate the benefits on a per acre basis. Moreover, the focus is on rangeland soil conservation, since it has the greatest potential benefits.

Table 5 and Figure 23 summarize the expected off-site benefits per acre of rangeland receiving proper grazing management. The expected benefits range from \$4/acre to \$64.58/acre for class VI land and from \$2.80/acre to \$66.31/acre for class VII land. Within each MLRA, the potential returns per acre are greatest on class VII land, with the exception of MLRA 70.

Calculations using the T-factor show a range of off-site benefits from \$1.09/acre to \$28.08/acre for land with erosion rates greater than T and from \$0.57/acre to \$21.98/acre for land with erosion rates greater than 2T.

MLRA 42 stands out as having the greatest potential benefits per acre regardless of how the benefits are computed. Moreover, if per acre costs of conservation are \$20 or less, then rangeland conservation would pay in terms of off-site benefits alone in MLRA's 48/51, 42, and 77.

## CONCLUSIONS

The following conclusions follow from the analysis:

- Off-site costs of wind erosion are a diminishing function of the erosion rate and the value of property at risk.
- 2. Over 55 percent of the off-site costs of wind erosion are incurred in MLRA 42 and, within MLRA 42, Bernalillo County accounts for nearly 50 percent of the damages. In fact, Bernalillo County accounts for nearly 28 percent of the state's off-site costs of wind erosion.
- 3. Nine counties have annual off-site costs in excess of \$20 million: Bernalillo, Valencia, McKinley, Sandoval, San Juan, Dona Ana, Eddy, Lea and Curry counties. At the other end of the spectrum, twelve counties have off-site costs of less than \$5 million: Union, Sierra, Hidalgo, Taos, Guadalupe, Catron, DeBaca, Harding, Mora, Colfax, Los Alamos and Ciboloa counties.
- 4. Population growth alone will likely increase annual offsite costs of wind erosion in New Mexico from the present level
  of nearly \$466 million to over \$578 million by the year 2005.
  Off-site costs in Bernalillo County are projected to increase
  from nearly \$129 million to over \$156 million by the year 2005.
- 5. The returns from reducing wind erosion increase at an increasing rate as the rate of erosion is reduced. For example, in MLRA 42 the last 0.1th ton/acre of erosion accounts for only \$1.2 million of off-site costs, but the first 0.1th ton/acre accounts for \$81.4 million.

- 6. The greatest returns from present soil conservation practices are on rangeland. The expected benefits range from \$4/acre to nearly \$65/acre on class VI land and from nearly \$3/acre to over \$66/acre on class VII land. Estimates of returns from class III and IV land are not possible due to insufficient data.
- 7. MLRA 42 stands out as having the greatest potential benefits per acre. Moreover, if conservation costs are \$20/acre or less, then rangeland soil conservation has benefits greater than costs in MLRA's 48/51, 42, and 77.
- 8. Since the damage function is not able to discriminate between sources of soil erosion by location, it may under estimate returns from soil conservation nearer population centers and over estimate returns from soil conservation further from population centers. That is, off-site benefits of soil conservation can be expected to decline with distance from cities.
- 9. Finally, while present soil conservation practices applied to untreated land have the potential to significantly reduce off-site costs of wind erosion, opportunities exist for new approaches to reduce wind erosion. For example, application of present soil conservation practices to untreated land in MLRA 42 could potentially reduce off-site costs by \$108 million, leaving over \$141 million of off-site costs that might be reduced by new approaches.
